

# Where is the frost line in the solar system

What is frost line in astronomy?

Thus, in astronomy, the frost line (also referred to as snow line or ice line) is the distance from the protostar where the temperatures are not high enough for volatile molecule (such as water, ammonia, or methane) to change from their original solid state (ice particles) into a gaseous state.

Where is the frost line?

For the water molecule, the frost line is a little less than 5 astronomical units (AU), or around 700 million kilometers from our sun, at which point the average temperature falls below 170 K (-103 °C). At this location, between Mars and Jupiter, water in its gaseous state will condense back into ice.

Which planets are located inside the frost line?

The frost line therefore separates terrestrial planets from giant planets in the Solar System. However, giant planets have been found inside the frost line around several other stars (so-called hot Jupiters). They are thought to have formed outside the frost line, and later migrated inwards to their current positions.

Why do we know where each frost line occurs?

Understanding where each frost-line occurs allows us to extrapolate the composition of the objects formed throughout the solar system. For example, Europa lying within Jupiter's orbit is mainly composed of rocks and water-ice as we are still too close from the Sun for other volatiles such as ammonia and methane to condense.

How far away is the frost line from the Sun?

The location of the "frost line" is also a matter of some debate, but current thinking holds that it is probably about 4 AU from the Sun. A great deal depends on how much solar radiation can penetrate deep into the outer parts of the primordial Solar Nebula.

Does the frost line determine a rocky or gas planet?

In the current solar system, the frost line is at about 5 AU, which is a bit closer than Jupiter, so currently all the rocky planets are inside the frost line, and all the gas giants are beyond the frost line. This would seem to imply that it's the frost line that determines whether a rocky or gas planet will form.

The location of the "frost line" is also a matter of some debate, but current thinking holds that it is probably about 4 AU from the Sun. A great deal depends on how much solar radiation can ...

Which statement is not thought to be true of all comets in our solar system? A. All comets orbit the Sun. B. Comets always have tails. C. All comets are leftover planetesimals that originally condensed beyond the frost line in the solar nebula. D. All comets are icy in composition.

Study with Quizlet and memorize flashcards containing terms like Which of the following statements about

## Where is the frost line in the solar system

comets and asteroids is true? A) Most of the trillions of comets in our solar system have tails. B) Comets are balls of ice and dust. C) All asteroids lie in the asteroid belt between Mars and Jupiter. D) Only asteroids collide with Earth. E) There are about 1 million ...

True or false: Within the frost line, planetesimals were composed entirely of rock and outside the frost line planetesimals were composed entirely of ice. 4 True or false: Based on our theory of how our own solar system formed, we would expect that other solar systems would be quite common.

Study with Quizlet and memorize flashcards containing terms like in essence, the nebular theory holds that, which of the following types of material can condense into what we call ice at low temperatures?, what do we mean by the frost line when we discuss the formation of planets in the solar nebula? and more.

At the time the solar system formed, ices and gases were stable farther out from the sun but not closer in. The line separating these two regions is called the frost line. Click Create Assignment to assign this modality to your LMS. We have a new and improved read on this topic.

The boundary between the colder outer solar system and the warmer inner solar system is called the Frost Line. There are specific frost lines for different volatiles which freeze at different ...

The frost line therefore separates terrestrial planets from giant planets in the Solar System. However, giant planets have been found inside the frost line around several other stars (so-called hot Jupiters). They are thought to have formed outside the frost line, and later migrated inwards to their current positions.

Asteroids formed inside the frost line, while comets formed outside. Where are the Trojan asteroids located? along Jupiter's orbit, 60° ahead of and behind Jupiter ... It is made of planetesimals formed in the outer solar system that were flung into distant orbits by encounters with the jovian planets. Rather than being a planet, Pluto is ...

Dividing these two regions is a frost line or ice line. Closer than the frost line material is too warm for ice to form. Farther than the frost line ice can form more readily. In the current solar system, the frost line is at about 5 AU, which is a bit closer than Jupiter, so currently all the rocky planets are inside the frost line, and all ...

What is the frost line of the solar system? the distance from the Sun where temperatures were low enough for hydrogen compounds to condense into ices, between the present day orbits of Mars and Jupiter. There are special planets in other solar systems called Hot Jupiters. These are gaseous planets that are found within 1.5AU of the star in ...

A. terrestrial planets sometimes form beyond the jovian planets B. ice-rich objects the size of terrestrial planets should exist in all solar systems C. this might have happened in our own solar system if it had taken longer for the solar wind to clear the solar nebula

## Where is the frost line in the solar system

without the sewers). In astronomy, the frost line (also referred to as snow line or ice line) is the distance from the Sun where the low temperatures encountered force a volatile molecule (such as water, ammonia, or methane) to revert into its solid state and form ice particles. For the water molecule, the frost line is a little less than 5 AU,

Study with Quizlet and memorize flashcards containing terms like A rocky leftover planetesimal orbiting the Sun is a) a meteor. b) a meteorite. c) a comet. d) an asteroid. e) possibly any of the above, Why do asteroids and comets differ in composition? a) Asteroids are much larger than comets. b) Comets formed from the jovian nebula, while asteroids did not. c) Asteroids and ...

The frost line in our solar system lies somewhere between the orbits of Mars and Jupiter. Here millions of asteroids orbit the sun. Most are very small but an estimated 750,000 have diameters greater than 1 km and perhaps 200 have diameters greater than 100 km; the largest being Ceres with a diameter of 940 km.

condense far from the Sun, beyond the frost line - Heavy ice/rock/metal objects in the outer solar system could capture lots of gas and became the jovian planets - Less heavy rock/metal objects in the inner solar system became the terrestrial planets

The "Frost Line" Rock & Metals can form anywhere it is cooler than about 1300 K. Carbon grains & ices can only form where the gas is cooler than 300 K. Inner Solar System: Too hot for ices & carbon grains. Outer Solar System: Carbon grains & ices form beyond the "frost line";.

The line separating these two regions is called the frost line. Click Create Assignment to assign this modality to your LMS. We have a new and improved read on this topic. ... At the time the solar system formed, ices and gases were stable farther out from the sun but not closer in. The line separating these two regions is called the frost line.

In the current solar system, the frost line is at about 5 AU, which is a bit closer than Jupiter, so currently all the rocky planets are inside the frost line, and all the gas giants are ...

A direct cribbing of the wiki's page for the frost line:. In astronomy or planetary science, the frost line, also known as the snow line or ice line, is the particular distance in the solar nebula from the central protostar where it is cold enough for volatile compounds such as water, ammonia, methane, carbon dioxide, carbon monoxide to condense into solid ice grains.

A. far beyond the orbit of Pluto B. in the inner solar system C. in the outer solar system beyond the frost line D. in the asteroid belt. in the outer solar system beyond the frost line -That is why they are icy leftovers from planet formation. See an expert-written answer!

Leftover planetesimals that formed in the region of the solar system now occupied by the jovian planets are called \_\_\_\_\_. Pieces of asteroids that have fallen to Earth are called \_\_\_\_\_. Leftover planetesimals that

## Where is the frost line in the solar system

formed inside the frost line are known as \_\_\_\_\_. Ceres, Pluto, and Eris are all round in shape and classified as\_\_\_\_\_.

Ceres is a dwarf planet covered by a dusty regolith (outer soil layer). No one is quite sure what is beneath that dust. The answer to the question may help astronomers to understand something about the early solar system.. Why It Matters. The placements of the planets in our solar system led scientists to an idea.; The hot sun drove off the ices and gases when the ...

Study with Quizlet and memorize flashcards containing terms like A rock found on Earth that crashed down from space is called \_\_\_\_\_, Which have the most elliptical and tilted orbits?, Leftover planetesimals that formed inside the frost line are known as and more.

The frost line for the Solar System lies between Mars and Jupiter. It marks a major divide in planet properties because outside of it, various kinds of frozen light molecules could accumulate on a forming planet as ices (for example, frozen water captures not only oxygen, but some hydrogen). These ices ran up the mass of the planet so it had a ...
